After studying the report, we must think about what we should do to avoid and reduce losses due to future earthquakes. In this paper, a simulation model and a finite element analysis was used to analyze the performance of a ship with a bow in the simulation of earthquakes. When this study is completed, the results will provide a theoretical basis for the design of the structure of ships. 4.1 Analysis of the Water Flow of the South Sea Current (from Wenchuan-Bay of Mudanjiang) For this, we need to analyze the flow of the water current between two adjacent islands. We begin the analysis of the flow of the current of the South Sea Current between Wenchuan and Mudanjiang. Wenchuan is a mountainous area in the east coast of China. It is known for its steep cliffs, where many rivers and creeks flow in a short space, leaving ample water in the area. In contrast, many of the other surrounding coastal cities have developed around the waterways, so many people are no longer dependent on the streams and rivers to provide water for drinking and living. However, the tidal range in the area is very large. Because of the geographic conditions, there are strong currents in the south, and there are low tides on the north. Although the daily tidal range is less than 0.5m, the tidal range can be as much as 7.5m. This makes the current difficult to control. Due to the strong currents in the area, many people died after losing their control of the current. People have been using rubber boats to control the current to avoid the problems in the area. The Government of Mudanjiang has designed a series of dams to control the tidal range in the area and set a new path for the development of the area. The current is controlled by three artificial islands in the river. This paper uses a computer model to simulate the flow of the current. 4.1.1 Problem Formulation The water current in Wenchuan flowed through the dam in Mudanjiang, so we can assume that the water current only flows in the dam and the channel along the dam. 82157476af
